(34) Programmable low-impedance interconnect circuit element and method of forming thereof.

(57) A programmable interconnect device for use in integrated circuits comprises a first conductive layer, an insulating layer over said first conductive layer, and a second conductive layer over said insulating layer. There is described the application of a programming voltage to cause the formation of at least one controlled radius filament formed from at least one of said first or second conductive layers, this may have a resistance of less than 300 Ohms. Suitably, the first conductive layer may be a polysilicon and the insulating layer a silicon nitride. The invention also relates to the method of forming such a circuit element on a substrate in a CMOS or bipolar application process.

EP 0 250 078 A2

PROGRAMMABLE LOW IMPEDANCE INTERCONNECT CIRCUIT ELEMENT AND METHOD OF FORMING THEREOF

BACKGROUND

1. Field of the Invention

The present invention relates to the field of integrated electronic circuit technology. More particularly, the invention relates to a reliable and manufacturable capacitor-like, electrically-programmable interconnect device to be used in integrated circuits.

2. The Prior Art

Integrated electronic circuits are usually made with all internal connections set during the manufacturing process. However, because of high development costs, long lead times, and high manufacturing tooling costs of such circuits, users often desire circuits which can be configured or programmed in the field. Such circuits are called programmable circuits and they usually contain programmable links. Programmable links are electrical interconnects which are either broken or created at selected electronic nodes by the user after the integrated device has been fabricated and packaged in order to inactivate or activate respectfully the selected electronic nodes.

Programmable links have been used extensively in programmable read only memory devices (PROMs). Probably the most common form of programmable link is a fusible link. When a user receives a PROM device from a manufacturer, it usually consists of an X-Y matrix or lattice of conductors or semiconductors. At each cross-over point of the lattice a conducting link, called a fusible link, connects a transistor or other electronic node to this lattice network. The PROM is programmed by blowing the fusible links to selected nodes and creating an open circuit. The combination of blown and unblown links represents a digital bit pattern of ones and zeros signifying data which the user wishes to store in the PROM.

Such fusible link PROM systems present certain disadvantages. For instance, because of the nature of the conducting material in the link, relatively high voltage and high current levels are needed during programming to guarantee the complete blowing of the fusible links. Since the link is usually conductive, it needs large amounts of power dissipation to blow it. Also, the shape and size of the fusible link must be precise so that the link will function freely as a conductor if it is not blown

and will be a completely open circuit if it is blown. Therefore, very critical photolithographic steps and controlled etch techniques are required during the manufacturing process of fusible link PROMs. Finally, a large gap must be blown in the link in order to prevent it from later becoming closed through the accumulation of the conducting material near the blown gap. Fusible link memory cells are relatively large in order to accommodate the link and its associated selection transistor and, therefore, fusible link PROM systems have high manufacturing and material costs and take up large amounts of chip real estate space.

In recent years, a second type of programmable links, called anti-fuse links, have been developed for use in integrated circuit applications. Instead of the programming mechanism causing an open circuit as is the case with fusible links, the programming mechanism in anti-fuse circuits creates a short circuit or relatively low resistance link. Anti-fuse links consist of two conductor and/or semiconductor materials having some kind of a dielectric or insulating material between them. During programming, the dielectric at selected points in between the conductive materials is broken down by predetermined applied voltages, thereby electrically connecting the conducting or semiconducting materials together.

Various materials have been suggested for the dielectric or insulating layer. Some of these suggested dielectric materials require a relatively high current and voltage during programming, require complex manufacturing techniques, and have low reliability during programming because it is difficult to control the reproducibility of the conductive state due to the nature of the crystalline structures of the materials involved. In addition, the programming process results in a link having a finite resistance in the order of several hundred to several thousand ohms. This characteristic of the known anti-fuse elements renders them relatively unsuitable for use in high speed circuits.

Some of the proposed dielectric insulators are doped amorphous silicon alloys, polycrystalline resistors, oxides, titanate of a transition metal, silicon oxide, aluminum oxide and cadmium sulfide. The problem with these approaches, have been related to the need of a high current and voltage to program and the difficulty to manufacture and control their reliability in both the on and off states. Materials such as cadmium sulfide, aluminum oxide and titanate, are complicated technology difficult to

manufacture with standard semiconductor processing. Capacitors with silicon oxides used as a dielectric do not produce a low enough impedance after programming.

Examples of known anti-fuse elements are found in the prior art. Reference is made to: U.S. Patent No. 3,423,646 which uses aluminum oxide, cadmium sulfide; U.S. Patent No. 3,634,929 which uses single film of Al_2O_3 , SiO_2 , and Si_3N_4 ; U.S. Patent No. 4,322,822 which uses SiO_2 ; U.S. Patent No. 4,488,262 which uses oxide or titanate of a transition metal; U.S. Patent No. 4,499,557 which uses doped amorphous silicon alloy; U.S. Patent No. 4,502,208 which uses SiO_2 ; U.S. Patent No. 4,507,757 which uses SiO_2 ; U.S. Patent No. 4,543,594 which uses SiO_2 .

Most of the above patents either describe complicated technologies or need high breakdown voltages and currents, and/or are difficult to manufacture or do not meet the reliability requirements of state-of-the-art integrated circuits in both the on and off states. These patents do not disclose the creation of controllable conductive filaments with low resistance after programming.

Other problems associated with existing dielectric materials in anti-fuse links include large memory cells, complex manufacturing processes of the unblown anti-fuse elements.

OBJECTS AND ADVANTAGES

An object of the present invention is to provide an electrically programmable low-impedance interconnect element.

Another object of the present invention is to provide an electrically programmable interconnect element which may be programmed with sufficiently low voltages and currents compatible with state-of-the-art MOS technology, resulting in a low impedance in the on-state.

Another object of the present invention is to provide an electrically-programmable interconnect element which is manufacturable using standard semiconductor processing and has high reliability in both the on and off states.

Advantages associated with the present invention in some or all of its embodiments include an interconnect which can be made with standard semiconductor manufacturing techniques, small size, a high reading current after programming, a manufacturing process with a minimal number of steps, and a controlled radius interconnect filament through the dielectric resulting in a repeatably manufacturable controlled low resistance link after programming. Furthermore, the present invention is

characterized by high reliability in both the programmed and unprogrammed state. Other and further advantages of the present invention will appear hereinafter.

SUMMARY OF THE INVENTION

An electrically Programmable, Low-Impedance Circuit Element after programming ("PLICE") is described. It consists of a capacitor-like structure with very low leakage current before programming and a low-resistance after programming.

This PLICE element is formed by having a dielectric between two conductive electrodes. In a preferred embodiment, one or both of the two conductive electrodes may be made of a high electromigration immunity material and may be formed from either heavily doped polysilicon, heavily doped single crystal silicon, or refractory metal such as tungsten, molybdenum, platinum, titanium, tantalum, or their silicides or a sandwich of polysilicon and metal. Those of ordinary skill in the art will recognize that the metal may be any substance used to provide interconnect in integrated circuits or is used as a diffusion barrier. In addition, it is believed that combinations of the above material will function in the present invention. In other embodiments, lower electromigration immunity materials may be used as long as the current passed through the PLICE after programming is appropriately limited to assure proper lifetime.

The dielectric layer, single or composite, between the two electrodes is such that when it is disrupted by a high electric field it will facilitate the flow of one of the two electrodes to produce a controlled radius conductive filament during its breakdown. It requires a low amount of charge fluence to breakdown at the higher programming voltage with practically used voltages and currents in integrated circuits. It also has a large enough charge fluence to breakdown at normal operating voltages to be a reliable circuit element during operation in its off state.

During programming, as the applied voltage reaches the dielectric breakdown, a localized weak spot in the dielectric starts to carry most of the leaking current and heats up which, in turn, increases the leakage current. A thermal runaway condition develops which results in localized heating and melting of the dielectric and adjacent electrode material. The conductive material flows from one of the two electrodes and forms a conductive filament shorting both electrodes. The thickness of this electrode should be sufficient not to cause any discontinuity or pits during the filament formation. The final radius of the filament depends on the composition and thickness of the dielectric, the

electrode conductive material melting temperature, and the energy dissipated during programming. Lower final resistance of this element after its programming can be obtained with a larger radius and a lower resistivity of the formed filament and a lower spreading resistance of both electrodes. A larger filament radius and higher electromigration immunity of the conductive electrode material that flows to form the filament result in higher current carrying capacity of the programmed element without blowing open due to electromigration.

In a preferred embodiment one of the conductors, the top electrode, is formed of heavily doped polysilicon of either $n+(p+)$ or is a sandwich of said polysilicon and a metal above it and the other conductor, the lower electrode, is formed of heavily doped equal polarity $n+(p+)$ diffusion region in a substrate or a well of opposite polarity $p(n)$. The dielectric in this embodiment is a tri-layer sandwich formed of a bottom oxide layer of 20A-50A, a central silicon nitride layer of 40A-100A, and a top oxide layer of 0A to 50A.

The PLICE element in the first preferred embodiment is programmed by applying a current controlled voltage source across the two conductors (electrodes). The composition of the composite dielectric is such that the structure provides an on-resistance of less than 300 ohms after programming and an off-resistance of more than 100 Mohms before programming. The structure requires a programming pulse of magnitude less than 30 volts, a time duration of less than 100 mSec while supplying a current of less than 10 mAmps. The size of the conductive filament is a function of the programming pulse and the composition of the composite dielectric structure and its radius is in the range of .02 μm to 0.2 μm .

In a second and third embodiment of the PLICE element, the PLICE element or capacitor anti-fuse is between two conductors (metal lines or polysilicon lines). This facilitates the interconnect between two conductors without using the silicon substrate as a path. Hence, the substrate can be used for active devices.

Those of ordinary skill in the art will recognize that the technology of this invention is compatible with and may be applied to any semiconductor structure or process.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a cross-section of a preferred embodiment of a PLICE element fabricated on a semiconductor substrate material in accordance with the present invention.

FIG. 2a is a cross-section of an alternative embodiment of a PLICE element according to the present invention having one metal electrode and one polysilicon electrode.

FIG. 2b is a cross-section of an alternative embodiment of a PLICE element according to the present invention having two metal electrodes.

FIG. 3 is a simplified cross-section of a PLICE element after programming.

FIG. 4 is a cross-section of a PLICE element like the embodiment disclosed with respect to FIG. 1, fabricated on a semiconductor substrate material wherein semiconductor material is employed as the electrically conducting material.

FIGS. 5a and 5b are schematic diagrams of the equivalent circuit of the PLICE element before and after programming.

FIGS. 6a-6f show a typical process for fabricating a PLICE element as a part of a silicon gate CMOS process.

FIG. 7 illustrates how the present invention may be incorporated into a typical bipolar process.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring first to FIG. 1, a preferred embodiment of the present invention is fabricated on a semiconductor substrate 10. Those of ordinary skill in the art will readily recognize that substrate 10 may in fact be a well region of one conductivity type fabricated in a semiconductor substrate of opposite conductivity type as is common in a CMOS process. In this embodiment, the bottom electrode is a heavily doped diffusion area in substrate 10 and may be for example from 1×10^{19} to 1×10^{21} atom/cm³ of arsenic or phosphorus if N-type. Bottom electrode 12 may be placed on substrate 10 by any of the known methods for creating such regions. It should be noted that bottom electrode 10 is heavily doped using a dopant which will create a semiconductor conductivity type opposite in polarity to that of the substrate 10. Therefore, if substrate 10 is P-type material bottom electrode 12 should be heavily doped N-type diffusion and vice versa.

In this embodiment the insulating dielectric layer is a composite layer comprising oxide layer 14, silicon nitride layer 16 and top oxide layer 18. The dielectric layer may also be formed of a single insulator material which facilitates the flow of one of the electrodes when disrupted by a high electric field to create a controllable filament radius.

Top electrode 20 is formed from a material of equal polarity as the bottom electrode, so if the bottom electrode is N-type then top electrode may be formed of heavily doped N-type polysilicon hav-

ing a sheet resistance of approximately 10 to 100 ohms/square. The thickness of the polysilicon may be from approximately 500 to 10,000 Angstroms, and may be approximately 4500 Angstroms in a preferred embodiment.

The top electrode 20 may also be a sandwich of said polysilicon layer and on top of it a conductive metal layer of Aluminum approximately 5,000 to 15,000 Angstroms.

In this embodiment, the thickness of the bottom oxide layer 14 of the composite dielectric is from 20 to 50 Angstroms, the thickness of the central silicon nitride layer is from 40 to 100 Angstroms, and the thickness of the top oxide layer 18 is from 0 to 50 Angstroms. The relative thickness of these layers are essential for manufacturing a reliable PLICE and a controlled filament of specific radius and conductivity as will be disclosed further herein.

The PLICE element of this embodiment is programmed by applying a current-controlled voltage source across the two electrodes. The composition of the composite dielectric is such that the structure provides an on-resistance of less than 300 ohms after programming and an off-resistance of more than 100 mega ohms before programming. The structure requires a programming pulse of magnitude less than 30 volts, a time duration of less than 100 mSec at a current of less than 10 mAmps. The size of the conductive filament is a function of the programming pulse and of the composition of the composite dielectric structure and its effective radius is in the range of from 0.2 μ m to 0.2 μ m.

As an example, a PLICE element having an N-diffusion of 1×10^{21} atoms/cm lower electrode, a 4500 Angstrom highly-doped polysilicon upper electrode having a sheet resistance of 18 ohms/square, and a dielectric consisting of a first layer of approximately 40 Angstroms of Silicon dioxide (SiO_2), a second layer of approximately 70 Angstroms of silicon nitride (Si_3N_4), and a third layer of approximately 15 Angstroms of SiO_2 will produce a filament having an effective radius of approximately 0.05 microns if programmed with a pulse of approximately 18v and a current of 1.0 mA for 100 mSec of duration. It has been found that the resulting filament resistance is less than 40 ohms. For the same 18V programming voltage and 100 mSec of programming time, a current of 0.2mA and 10mA will produce a filament with effective radius from 0.04 microns to 0.2 microns.

It will be appreciated by those skilled in the art that conductivity of the dopants of substrate 10 lower electrode 12 and upper electrode 20 may be reversed i.e. substrate 10 may be N-type material and lower and upper electrodes 12 and 20 may be heavily doped P material.

Referring now to FIGS. 2a and 2b, an alternate embodiments of the PLICE will be disclosed wherein the two electrodes are above the substrate. These embodiments facilitate the interconnect between two conductors without using the silicon substrate as a path. Hence, the substrate can be used for active devices.

Referring first to FIG. 2a the bottom electrode 40 of the PLICE element is fabricated of polysilicon which may be from approximately 500 to 10,000 Angstroms thick covered by a silicide layer 42, which may be from approximately 100 to 5000 Angstroms thick. This reduces the sheet resistance of the polysilicon to less than approximately 10 ohms. Silicide layer 42 also serves to provide the molten substance which will create the filament through the dielectric. Silicide layer 42 may be of a silicide of tungsten, molybdenum, titanium or tantalum. Insulating oxide regions 44 are shown in FIG. 2a to indicate the type of environment which may be typically provided to isolate the PLICE element from other circuit elements on the silicon substrate.

Dielectric layer 46 is placed over the silicide layer 42 and also overlaps field oxide region 44. Dielectric layer 46 of the embodiment of FIG. 2a may be the sandwich structure disclosed with respect to the embodiment of FIG. 1. Dielectric layer 46 may also be formed of a single silicon nitride layer approximately 100-2000 Angstroms thick.

A barrier metal layer 48, such as titanium, tungsten, or titanium nitride is placed in between dielectric 46 and top electrode 50 (which may be made of aluminum) to prevent the diffusion of the material of the top electrode into the filament that is formed after programming. Barrier metal layer 48 may be from approximately 50 to 5000 Angstroms thick.

Turning now to FIG. 2b the PLICE element of this embodiment has a lower electrode 60 which may be a metal such as aluminum, covered with a layer of barrier metal, such as tungsten, titanium, or titanium nitride to prevent the diffusion of the aluminum metal into the filament as discussed with respect to FIG. 2a. Insulating oxide regions 64 are shown as a method to isolate the PLICE element from other circuit elements on the silicon substrate. A layer 66, preferably formed of tungsten silicide is interposed between barrier metal layer 62 and dielectric layer 68 through which the filament will be formed. Layer 66 is used to provide the molten substance from which the filament will be formed when the PLICE element is programmed. A barrier metal layer 70 is interposed between dielectric layer 68 and top electrode 72, which may be a

metal such as aluminum in order to prevent the material of the top electrode from diffusing into the filament material. The thickness of the layer in the embodiment of FIGS. 2a and 2b may be similar.

The PLICE element of the embodiments depicted in FIGS. 2a and 2b may be programmed by application of a voltage from approximately 10 to 30 volts between the two electrodes depending on the thickness of the dielectric. The programming pulse should be at a duration of approximately less than 100 mSec and at a current of approximately less than 10mA.

Referring now to FIG. 3 a simplified cross-section of the PLICE element after programming, shows a lower electrode 80 and upper electrode 82 with a dielectric layer 84 interposed in between. A controlled-radius filament 86 has been caused to form in the dielectric layer and is composed of the electrode material. As will be readily understood by those of ordinary skill in the art, the radius of the conductive filament controls the on-resistance of the PLICE element after programming. The use of a high electromigration immunity material and a controlled radius filament results in adequate reliability with current flow and an immunity from the PLICE element causing itself to unprogram after considerable use due to electromigration of the filament material. As mentioned, lower electromigration immunity materials may be used so long as the operating current is below a value which will cause considerable electromigration of the filament material during the device lifetime.

The preferred embodiments of the PLICE element illustrated herein may be integrated into a standard integrated circuit technology using N+ polysilicon as the top electrode and using an N+ diffusion in a P substrate or P-well as the bottom electrode. This embodiment is discussed with respect to FIG. 4.

Referring now to FIG. 4, the PLICE element is constructed in P-substrate or P-well 100. Field oxide regions 102 isolate the PLICE element structure from other circuit elements. Heavily doped N+ diffusion region 104 forms the bottom electrode for the PLICE. Dielectric layer 106 separates lower electrode 104 from upper electrode 108 which may be heavily doped N+ polysilicon. Connections to lower electrode 104 and upper electrode 108 are shown schematically at 110 and 112 respectively. In the embodiment of FIG. 4 both the bottom electrode 104 and top electrode 108 can be contacted to metal layers to reduce interconnect resistance.

FIGS. 5a and 5b illustrate schematically the equivalent circuit of the PLICE before and after programming respectively. In FIG. 5a parasitic diode 120 inherently exists between the substrate

100 and N+ diffusion region 104 forming the lower electrode in FIG. 4. Off capacitor 122 represents the capacitor formed by lower electrode 104 and upper electrode 108.

After programming, parasitic diode 120 is now seen connected to resistor 124 which represents the inherent on-resistance of the controlled-radius filament formed during programming, which connects lower electrode 104 with upper electrode 108 and the spreading resistance of the top and bottom electrodes. In both FIGS. 5a and 5b the three terminals of the equivalent circuit are terminal 100, the substrate of FIG. 4, terminal 110 which is the equivalent terminal 110 in FIG. 4 and terminal 112 which is the equivalent terminal 112 of FIG. 4.

While the discussions involving FIGS. 4, 5a and 5b have assumed P substrates and N diffusions, those of ordinary skill in the art will readily recognize that N-type substrates or wells and P diffusions could be used as effectively. If that is the case it will be immediately recognized that diodes 120 of FIGS. 5a and 5b will have their anodes at terminal 110 and their cathodes at terminal 100.

As illustrated in FIGS. 6a-6f the preferred embodiments of the present invention are easily incorporated into standard silicon integrated circuit manufacturing processes. The disclosure herein relates to a CMOS process, but those of ordinary skill in the art will readily recognize how the PLICE formation could be incorporated into NMOS, PMOS or other processes.

First as shown in FIG 6a, the silicon wafers have been processed utilizing a standard CMOS silicon gate process to the point where the PLICE is to be incorporated in an appropriate area. Specifically, N-type substrate 150 has been prepared by creating boron channel stop implants 152, boron P-well 154, field oxide regions 156 and initial gate oxide layer 158 using conventional CMOS processing technology. A polysilicon layer has been created and defined to form gates 160 and 162 for N-channel and P-channel devices respectively.

The arsenic or phosphorus doping step for source/drain regions 164 of the N-channel device in P-well 154 also forms the first step for creation of the PLICE; since an extra aperture in photo resist mask 166 allows for doping the P-well 154 at region 168 to create the lower electrode of the PLICE simultaneously with the N-channel source/drain coping step.

The initial gate oxide layer 158 is then etched to the bare substrate and cleaned in preparation for growing dielectric layer 170.

Referring now to FIG. 6b, the dielectric layer 170 of the PLICE is next formed on the entire surface of the substrate. In a preferred embodiment, a first layer of silicon dioxide is either deposited or thermally grown. A silicon nitride layer is

next deposited using standard LPCVD or CVD techniques. A final layer of silicon dioxide is then either deposited or thermally grown. The processes used to form these layers may be conventional processing steps known to those skilled in the art.

Referring now to FIG. 6c, a layer polycrystalline silicon region 172 is then formed over the entire surface of the wafer. Region 172 may be fabricated with standard LPCVD or CVD techniques. Referring to FIG. 6c, a photomask 174 has been used to delineate the polycrystalline silicon layer 172 to form the upper electrode of the PLICE. This shaped upper electrode 176 is then used as a mask to selectively remove the silicon dioxide/silicon nitride/silicon dioxide dielectric sandwich insulating layer from areas outside of the PLICE structure. The structure is then sealed with a thin thermal oxide layer 178, as shown in FIG. 6d.

The process of manufacturing the remainder of the CMOS circuit can then continue in a standard manner to form the finished device as illustrated in FIG. 6e. The boron source and drain regions 180 and 182 for the P-channel devices are implanted, using a photomask 184 and the portion of polysilicon gate layer 162 to protect the areas outside the implant regions. Referring to FIG. 6f, a polysilicon glass passivation layer 186 is deposited, flowed and contact cuts are made. Metal layer 188 is then deposited and delineated making connections to the transistors PLICE nodes. If dual layer metal is to be used, an interlayer dielectric is deposited and a second layer of metal is deposited, delineated and annealed (not shown). Finally, a passivation layer is deposited for scratch protection and the metal pads are opened.

The PLICE element can also be applied to bipolar process for either PROM cells or programmable logic devices. The preferred embodiment would be the same as the CMOS embodiment. Such a process is disclosed in conjunction with FIG. 7. The process would begin as a conventional bipolar process, first the buried layer would be defined and diffused in, followed by the epitaxial deposition and isolation process. There are several methods for performing isolation and diffusion, all of which will work with the PLICE element. The base region would then be defined and diffused. The emitter would then be defined and diffused followed by the contact cuts. This is the preferred point where the PLICE element could be defined by forming the dielectric, followed by the poly deposition, doping and delineation. The underlying dielectric would then be removed from the unwanted areas utilizing the poly as mask. Following the definition of the PLICE element the metalization process would proceed as normal. Either single or dual metal processes may be used.

While embodiments and applications of this invention have been shown and described, it would be apparent to those skilled in the art that many more modifications are possible without departing from the inventive concepts herein. The invention, therefore, is not to be restricted except in the spirit of the appended claims.

Claims

1. A programmable low impedance interconnect circuit element, including:

a first conductive layer;

an insulating layer over said first conductive layer, and

a second conductive layer over said insulating layer, wherein the application of a programming voltage causes the formation of at least one controlled radius filament formed from at least one of the said first or second conductive layers having a resistance of less than 300 ohms.

2. A programmable low impedance interconnect circuit element, including:

a first conductive layer;

an insulating layer over said first conductive layer, said insulating layer having a first silicon dioxide portion and a second silicon nitride portion over said first silicon dioxide portion, and

a second conductive layer over said insulating layer.

3. The programmable low impedance interconnect circuit element of claim 2 wherein said insulating layer further includes a third silicon dioxide portion over said second silicon nitride portion.

4. The programmable low impedance interconnect circuit of claim 2 or 3 wherein said insulating layer contains at least one controlled-radius filament of conductive material formed from at least one of said first or second conductive layers extending therethrough and in electrical contact with said first and second conductive layers.

5. The programmable low impedance interconnect circuit of claim 1, 2, 3 or 4, wherein at least one of said conductive layers is formed of a material having a high electromigration immunity.

6. The programmable low impedance interconnect circuit of claim 1, 2, 3, 4 or 5, wherein at least one of said conductive layers is heavily doped polysilicon.

7. The programmable low impedance interconnect circuit of claim 1, 2 or 3, wherein said first conductive layer is a diffusion and wherein said second conductive layer is heavily doped polysilicon having the same polarity as said diffusion.

8. The programmable low impedance interconnect circuit of claim 7, wherein said second conductive layer is covered by a metal layer.

9. The programmable low impedance interconnect circuit of claim 1, 2 or 3, wherein said first and second conductive layers are a metal.

10. The programmable low impedance interconnect circuit of claim 2, wherein said first conductive layer is a diffusion and wherein said second conductive layer is a sandwich of heavily doped polysilicon layer having the same polarity as said diffusion under a metal conductive layer.

11. A programmable low impedance interconnect circuit element including:
a first conductive layer,
a silicide layer covering said first conductive layer,
an insulating layer covering said silicide layer, a
metal layer covering said insulating layer.

12. The programmable low impedance interconnect circuit element of claim 11, further including a barrier metal layer in between said insulating layer and said metal layer.

13. The programmable low impedance interconnect circuit element of claim 11, wherein said first conductive layer is a metal or a sandwich of a metal and a barrier metal.

14. The programmable low impedance interconnect circuit element of claim 11, 12 or 13, wherein said first conductive layer is a polysilicon.

15. The programmable low impedance interconnect circuit element of any one of claims 11 to 14, wherein said insulating layer is a silicon nitride.

16. The programmable low impedance interconnect circuit element of any one of claims 11 to 15, wherein said insulating layer contains at least one controlled-radius filament of conductive material extending therethrough and in electrical contact with said silicide layer and said conductive metal or metal with barrier layer.

17. A method of forming a programmable low impedance interconnect circuit element on a substrate in a CMOS fabrication process including the steps of:

defining and doping with a first conductivity type, a first region in said substrate for forming the lower electrode of the programmable low impedance circuit interconnect element simultaneous with a definition and doping of the regions for doping source drain regions in said substrate,
removing the initial gate oxide layer in said first region,

depositing a dielectric layer for said programmable low impedance circuit interconnect element over said region,

depositing a conductive layer to form the upper electrode for said programmable low impedance circuit interconnect over said dielectric layer,
defining said conductive layer and said dielectric layer,

continuing said CMOS process sequence.

18. The method of claim 17 wherein the conductive layer to form the upper electrode is fabricated of polysilicon having a conductivity type the same as said first region.

19. A method of forming a programmable low impedance interconnect circuit element in a bipolar fabrication process including the steps of:
defining a region in the emitter for use as the lower electrode of the programmable low impedance circuit element,
forming a dielectric layer over said defined region,
depositing an upper electrode conductor region,
defining said upper electrode conductor region and said dielectric region,
continuing said bipolar fabrication process sequence.

20. The method of claim 19 wherein said upper electrode conductor region is fabricated of polysilicon having a conductivity type the same as said emitter.
